As teachers, we constantly tweak our lessons, making them more appropriate for our students. I considered a new technique for factoring trinomials when I heard questions in class regarding why we would multiply $a$ and $c$ as well as statements about how unconnected doing so was from the prior strategy when $a = 1$. However, it really hit me when my standards-referenced quiz scores for factoring and solving quadratic equations with a leading coefficient not equal to 1 came in and the average score was 69 percent correct. Something needed to change.

**THE ISSUE**

One of the foundational topics in first-year algebra concerns the concept of factoring. Students first consider factoring quadratic expressions of the form $x^2 + bx + c$ by searching for two factors of $c$ whose sum is $b$. Generally, students can become successful with these types of problems and explain the steps they are taking. However, the same cannot be said when a leading coefficient other than 1 is introduced into the problem. More explicitly, factoring $ax^2 + bx + c$ with $a \neq 1$ (and going...
forward $ax^2 + bx + c$ will mean $a \neq 1$ proves to be much more difficult for students. This is perhaps mainly because current textbooks present this topic in a completely different fashion from the way they approach the situation when $a = 1$.

We discuss an alternative strategy for factoring quadratics of the form $ax^2 + bx + c$, known as factoring for roots. This strategy enables students to extend the knowledge they used when the leading coefficient was 1 and explain the steps they are taking in solving. Many other current strategies fail in both these endeavors.

**THE EASY STYLE**

Traditionally, students begin the study of factoring of quadratics by multiplying binomials such as $(x + 2)(x + 3)$ and producing an answer of $x^2 + 5x + 6$. Traditionally, students are able to rely partly on this algebraic demonstration, some use manipulatives, such as algebra tiles or a modified version of algebra tiles by constructing an area model (see Fig. 1). However, this concept of factoring quadratics when the leading coefficient is 1 has never been the biggest problem with factoring in the algebra curriculum. Quadratics with a leading coefficient of 1 challenge some students’ factoring abilities, but expressions with a leading coefficient not equal to 1 tend to frustrate even the most proficient.

**PROBLEM: WHEN $a \neq 1$**

Factoring expressions of the form $ax^2 + bx + c$ is noticeably more difficult than factoring $x^2 + bx + c$ because there are multiple strategies to attack this new challenge. The lack of consensus in the textbooks’ approaches to the setting only compounds this problem. In Algebra 1: A Common Core Curriculum, Larson and Boswell suggest making a table to guess and check all the possible factored forms based on the factors of $a$ and $c$ until one also produces the correct value for $b$ (see Table 1).

I can already sense the audible groans of frustration that a student would generate upon being presented with this strategy. It is cumbersome and tedious for students and unfair to teachers asked to present it. Can you imagine explaining this strategy to an absent student for a problem such as $12x^2 – 23x – 24$? Such a table would consist of 48 rows and 4 columns! I also know that some teachers discuss the concept of considering all the possibilities for such situations as $2x^2 – 3x – 20$ without committing to paper and pencil. However, I cannot show all students how this mental game plays out because it is done as a whole class. I cannot show all students how this mental game plays out because it is done strictly in one’s head. I can give them strategies and show example after example, but not all students have obtained the number sense that is required for this mental exercise at this stage of their development. Textbooks recognize this, which is why they present the table method.

McGraw-Hill’s Algebra 1 presents two strategies: (1) the same guess-and-check strategy as above and (2) a version of factoring by grouping where one splits the middle term by finding two numbers whose sum is $b$ and whose product is $ac$. Let’s see how this strategy works with $4x^2 – 23x + 15$. We need to find two numbers whose sum is $–23$ (since we will be splitting the middle term) and whose product is $4 \times 15 = 60$. The text explains neither why this strategy works nor where the idea comes from. The students would note that we have a leading coefficient other than 1 and a product of 60, but they are not told why this strategy alleviates this situation.

Unfortunately, once students master a procedural tool without yet acquiring the appropriate conceptual understanding to accompany it, they have little motivation to seek out justification because the procedure works (Hebert 1998). To combat this, the authors of Adding It Up (NRC 2001) state that conceptual understanding, the “how” and “why” the method works, should be present in all phases of the procedural teaching.

**PROCEDURAL FLUENCY AND CONCEPTUAL UNDERSTANDING REQUIRED**

The NCTM position statement concerning procedural fluency defines it as the—ability to apply procedures accurately, efficiently, and flexibly; transfer procedures to different problems and contexts; to build or modify procedures from other procedures; and to recognize when one strategy or procedure is more appropriate to apply than another.

Other versions of this method exist (one well-known example is called Bottoms Up or Slip-Slide Factoring), and I highly recommend Jeffrey Steck roth’s (2015) wonderfully informative article on Slip-Slide Factoring from a transformational point of view. However, these techniques all rely on the step where one needs two numbers whose product is $ac$. The problem is that the justification for this method is both extremely involved for a first-year algebra student to comprehend and some teachers to defend, and it bears little to no resemblance to the strategy when $a = 1$. Alas, in some texts the justification is barely absent. Mathematics educator John A. Van de Walle and his colleagues (2014, p. 1) state:

One hallmark of mathematical understanding is a student’s ability to justify why a given mathematical claim or answer is true or why a mathematical rule makes sense.

More often than not when procedural fluency trumps conceptual understanding, a student’s mathematical comprehension is incomplete.

**Factoring expressions with a leading coefficient not equal to one tend to frustrate even the most proficient.**

![Fig. 1](image1.png)

**Fig. 1** Students can use algebra tiles and an area model representation when multiplying binomials, as in this example for $x^2 + 5x + 6$. **Fig. 2** Factoring a quadratic expression by grouping if no justification for the first step is discussed (adapted from Carter et al., 2010, p. 510).
Fig. 3 Using an area model to factor a quadratic with fractions helps students keep ideas organized.

We could factor out a 2, and now we are at 2(x² – 5 x/2 – 12/2).

We know how to address this because the leading coefficient inside the parentheses is now 1. We need two numbers whose product is –12/2 and whose sum is –5/2. If they have a sum of –5/2, we know that in factored form, it will look like 2((x + 5/2)(x – 7/2)).

However, when we do so, it becomes apparent that these halves will produce fourths when we recombine c, so we rewrite c as –24/4 and get 2((x² – 5 x/2 – 12)/4).

Since we have addressed the denominators, we need consider only the numerators. Therefore, we factor out the 12, and then adjust the final term:

2((x² – 23 x/12 – 24/12)–(24/12))

Now, with the denominators accounted for, produce two numbers whose product is –288 and whose sum is –23. One might begin with combinations –144 and 2, –72 and 4, –48 and 6, and –36 and 8 but find that all are too far apart (actually, realizing they must sum to –23 would eliminate some of these earlier choices for proficient students). The last option of –36 and 8 sums to –28, so it is close. Next, try –32 and 9 and find success:

y = 12((x² – 23/12 x – 24/12)

Our final step is to rewrite its final term an equivalent fraction by multiplying by a/b.

For this, we need two numbers whose sum is –8 and product is –20 since the sum of fourths is still fourths but the product of fourths is sixteenths. Our numbers are 2 and –10.

</tbody>
</table>

With the fact that two seemingly identical scenarios, factoring when a is or is not 1, would have such different approaches. This case-by-case analysis left them frustrated, and their average quiz score of 69 percent (sample size of 38 and standard deviation of 2.85) on this skill reflected their exasperation.

The next spring, I introduced the technique of factoring for roots. Using the same questions as the previous year with no other additional supports, the quiz scores had an average of 83 percent (with a sample size of 41 and a standard deviation of 2.12). I knew I was on to something. I could see students’ work support the steps they were taking (see fig. 4). There were no leaps of faith; their mathematics built on a solid foundation of prior knowledge and conceptual understanding.

EXPANDING OLD KNOWLEDGE TO CREATE NEW KNOWLEDGE

Factoring for roots (see the steps in table 2) allows students to use the same strategy as when factoring x² + bx + c. This reutilization of prior knowledge reinforces the concept that mathematics is not a set of disconnected topics but rather interconnected ideas reinforced by one another. Students find it especially illuminating when we discuss how this not require my students to simplify from y = 2(x + 3/2)(x – 4) to y = (2x + 3)(x – 4).

We certainly discuss this simplification because students will never see anyone leave it as the former, but we also discuss why we care about factoring in the first place, which is to find x-intercepts. At this point in the year, my students have already solved such equations as 0 = x² – 6x + 8 by factoring, and they have graphed y = x² – 6x + 8 by factoring first to find the roots and then using the symmetry of the parabola to find its vertex. They know we factor an equation to find its roots, so the form y = 2(x + 3/2)(x – 4) makes it easier to find them. To further show the advantages of this method, my students articulated that they struggled with equations and not just expressions, I would reinforce the concept that mathematics is not a set of disconnected topics but rather interconnected ideas reinforced by one another. Students find it especially illuminating when we discuss how this
new strategy directly transforms to the old strategy in the case when $a \cdot c = c$ since $a = 1$.

A tangential benefit is that the new method allows students an opportunity to practice and refine arithmetic with fractions. This is important because, according to Siegler and his colleagues (2012), the ability to achieve competency in fraction multiplication and division is the number one predictor of high school mathematics achievement, even after controlling for factors such as overall intellectual ability, working memory, and socioeconomic status.

One might argue that Siegler and his colleagues predict achievement of high school students—and my students are already in high school. Those students who arrive not completely proficient in fraction arithmetic might make some serious gains by employing the factoring for roots strategy. Using fraction arithmetic as a fundamental tool to arrive at a more cognitively demanding mathematical abstraction may help them. Cognitive scientist Willingham states that students are more likely to remember concepts used to arrive at novel and more complex ideas than if the concept itself is the final learning outcome (2009).

Finally, factoring for roots does not leave itself vulnerable to a student using it without fully comprehending the mathematics behind the technique.

It ties procedural fluency and conceptual understanding together in such a way that students find the factoring for roots method useful and enlightening.

This is because factoring for roots requires correctly manipulating fractions. In this manner, it ties procedural fluency and conceptual understanding together in such a way that students find the factoring for roots method useful and enlightening. Compared with other techniques, factoring for roots is superior in three ways:

1. It builds on previous knowledge.
2. It is conceptually based.
3. It avoids case-by-case analysis.

Instead of mathematics being a disconnected set of procedures, this method attempts to combine two ideas that come from the same concept, factoring, whereas other textbooks and strategies push them further apart.
